A conserved function of YidC in the biogenesis of respiratory chain complexes

Martin van der Laan, Malene Urbanus, Corinne M. ten Hagen-Jongman, Nico Nouwen, Bauke Oudega, Nellie Harms, Arnold J.M. Driessen and Joen Luirink

Proceedings of the National Academy of Sciences of the United States of America **100**, 5801-5806 (2003)

Summary

The *Escherichia coli* inner membrane protein (IMP) YidC is involved in the membrane integration of IMPs both in concert with and independently from the Sec translocase. YidC appears to be dispensable for the assembly of Sec-dependent IMPs, and so far has only been shown to be essential for the proper Sec-independent integration of some phage coat proteins. Here we studied the physiological consequences of YidC depletion in an effort to understand the essential function of YidC. The loss of YidC rapidly and specifically induced the Psp stress response, which is accompanied with a reduction of the proton motive force. The latter is due to defects in the functional assembly of cytochrome *o* oxidase and the F₁F₀ ATPase complex, which is reminiscent of the effects of mutations in the *yidC* homologue *OXA1* in the yeast mitochondrial inner membrane. The integration of CyoA (subunit II of the cytochrome *o* oxidase) and F₀c (membrane subunit of the F₁F₀ ATPase) appeared exceptionally sensitive to depletion of YidC suggesting that these IMPs are natural substrates of a membrane integration and assembly pathway in which YidC plays an exclusive or at least pivotal role.

Introduction

Integration of inner membrane proteins (IMPs) in *Escherichia coli* can occur via different mechanisms. The majority of IMPs are targeted in a co-translational manner to the Sec translocase in the inner membrane by the signal recognition particle (SRP) and its receptor FtsY (reviewed in 109). The Sec translocase consists of the core channel components SecY, SecE and SecG that constitute a heterotrimer, and the peripheral motor protein SecA. In addition, SecD, SecF and YajC form an accessory complex that is loosely associated with the core translocase and facilitates the translocation process (reviewed in 157). Recently, YidC was identified as a novel factor that specifically interacts with transmembrane segments (TMSs) of nascent IMPs during membrane integration (213) and that is associated with the SecDFYajC subcomplex (187).

In contrast to the Sec-dependent IMPs, some small phage coat proteins, such as M13 procoat and Pf3 coat protein, were reported to insert ‘spontaneously’ into the membrane, i.e., independent of the Sec-translocase and the SRP targeting pathway (47, 139). Recently, this concept of unassisted integration was challenged by the observed requirement for YidC in Sec-independent IMP integration (205, 206).

YidC is an essential polytopic IMP homologous to the mitochondrial IMP Oxa1p and the thylakoid membrane protein Alb3. Both Oxa1p and Alb3 have been implicated in membrane protein insertion and are essential for correct organelle function (reviewed in 154, 220). Oxa1p is needed for the proper insertion of a subset of mitochondrially encoded IMPs, such as subunits of cytochrome *c* oxidase and F₁F₀ ATPase (104, 147, 220). Since mitochondria do not possess an SRP-like targeting pathway or a Sec-like translocase, it has been suggested that Oxa1p functions in a fashion similar to YidC in the Sec-independent route in *E. coli* (154, 220).

The exact role of YidC in the membrane integration of IMPs has not yet been defined but appears to be complex. YidC has been shown to interact specifically with the TMSs of the Sec-dependent IMPs such as FtsQ, leader peptidase (Lep), mannitol permease and YidC itself at various stages in the membrane integration process (17, 115, 116, 213, 230, 231, 241). This suggests a role in the lateral movement of TMSs from the Sec translocase into the lipid bilayer. In addition, YidC might function in the initial recognition and reception of TMSs since it contacts the TMS of Lep very early in biogenesis even before it is fully exposed outside the ribosome (116). Even though all

tested Sec-dependent IMPs interact with YidC during membrane insertion, YidC depletion only mildly affects the assembly of Sec-dependent IMPs (205, 230). In contrast, assembly of Sec-independent IMPs is severely impaired upon YidC depletion (205). M13 procoat appears to be able to target and bind to the inner membrane independently of YidC, but then requires YidC to translocate its periplasmic domain across the membrane whereupon it attains its correct topology (206).

Since YidC appears to be dispensable for assembly of Sec-dependent IMPs and known Sec-independent proteins that require YidC for proper integration are phage coat proteins, the question arises why YidC is essential for cell viability. To identify *E. coli* IMPs that require YidC for proper membrane biogenesis, we analyzed the physiological consequences of YidC depletion. We observed that depletion of YidC results in a rapid and massive expression of PspA. PspA is a stress protein that responds to a variety of membrane damaging treatments that ultimately result in a dissipation of the proton motive force (PMF) (reviewed in 169). Here we show that the PMF is strongly reduced upon depletion of YidC and that this relates to a decreased activity and defects in assembly of both cytochrome *o* oxidase and F₁F₀ ATPase.

Results

Depletion of YidC induces a strong and specific PspA stress response

To study why YidC is essential for cell viability, we analyzed the physiological consequences of YidC depletion. First, the effect of YidC depletion on the protein composition of the inner membrane was examined. IMVs were purified from strain JS7131 in which the YidC expression is under control of the *araBAD* operator/promotor (205). Cells were grown for 3.5 h in the presence of 0.1% arabinose (control cells, WT) or glucose (YidC-depleted cells), and used for the isolation of IMVs. As shown by immunoblotting, the amount of YidC in these IMVs decreased to an undetectable level when cells were grown under depleting conditions (Fig. 1B, upper panel). Analysis of the IMVs by SDS-PAGE and CBB staining revealed no dramatic changes in the overall protein profile except for the appearance of a protein of ~25 kDa in the YidC-depleted IMVs (Fig. 1A). This protein was

identified by immunoblotting as phage shock protein A (PspA; Fig. 1B, lower panel), a peripheral IMP with a predicted molecular weight of 25.6 kDa (reviewed in 169). Since PspA has been characterized as a stress protein that is induced under conditions that affect the integrity of the inner membrane, we examined the PspA levels at various time points during YidC depletion to determine whether PspA induction is an early effect of YidC depletion or perhaps a late effect due to accumulative membrane

Fig. 1: YidC depletion induces PspA expression. IMVs were isolated from JS7131 cells depleted of YidC (YidC↓) for 3.5 h or grown under control conditions (WT) as described in Materials and Methods. 10 µg of IMVs were analyzed by SDS-PAGE and stained with CBB (A), immunostained with αYidC (B, upper panel) or with αPspA (B, lower panel). The ~25 kDa protein PspA is indicated by ♦ (A). Effects of YidC depletion on the expression of stress-related proteins (C). Cells were depleted for 1.5, 2.5, 3.5 and 5h or grown under control conditions. 0.05 OD₆₆₀ units of cells were analyzed by immunoblotting using antibodies against YidC, PspA, DnaK, SecA and DegP. Effects of YidC depletion on the expression of translocase components (D). IMVs were isolated from cells depleted of YidC for 1.5, 2.5 and 3.5 h. 10 µg protein was analyzed by SDS-PAGE and immunoblotting using antibodies against YidC, SecY, SecE, SecD, and SecF.

damage. Cells were harvested after 1.5, 2.5, 3.5 and 5 h of depletion and whole cell samples were analyzed by immunoblotting to determine the YidC and PspA content (Fig. 1C). YidC was still detectable after 1.5 h of depletion but its signal decreased over time. PspA became well detectable after 2.5 h, when YidC was barely detectable. This indicates that PspA expression responds promptly to YidC depletion before significant effects on growth and cell morphology are observed (data not shown).

Next, we analyzed whether the response is specific for PspA or part of more general stress response. Cellular levels of three stress-related proteins were examined by immunoblotting: the cytosolic chaperone DnaK, the translocase component SecA, and the periplasmic chaperone/protease DegP. DnaK is a heat shock protein (150), SecA expression is induced upon secretion stress (188) and DegP expression responds to cell envelope stress (197). The levels of DnaK, DegP, and SecA levels did not change significantly upon YidC depletion (Fig. 1C). Taken together, the results indicate that YidC depletion results in a rapid, strong and specific increase in the expression of PspA.

Among the stimuli that induce the PspA response are conditional mutations in *secD*, *secF*, and *secA* (129) and depletion of SecE (Houben and Luirink, unpublished observation). Since part of YidC is physically associated with the Sec translocase (187, 213), we investigated whether YidC depletion influences the composition of the Sec translocase, which might indirectly stimulate PspA expression. IMVs derived from YidC-depleted and control cells were analyzed by immunoblotting to monitor the levels of the different translocase subunits (Fig. 1D). The levels of SecY, SecE, SecD and SecF were hardly affected at 2.5 h when the PspA response became detectable. After prolonged depletion of YidC the levels SecE, SecD and SecF did decrease slightly. These data strongly suggest that the induction of the PspA response is not caused by reduced levels of translocon components.

Depletion of YidC affects the PMF

The primary signal for the PspA response is considered to be a reduction of the PMF (169). PspA expression responds to uncoupling agents (169) and a *pspA* mutant strain was shown to be affected in maintenance of the PMF under PspA-inducing stress conditions (130). Therefore, it was of interest to investigate the effect of YidC depletion on the PMF. For this purpose, $\Delta\psi$ was measured in intact cells using a tetraphenylphosphonium (TPP⁺) selective electrode. Measurements were performed in

the presence of nigericin (a K^+/H^+ antiporter) and potassium to ensure that $\Delta\psi$ is the only component of the PMF. Cells were depleted for YidC for 1.5, 2.5 and 3.5 h and the outer membrane was permeabilized with EDTA. After 1.5 h of growth control and YidC-depleted cells show a similar, low uptake of TPP^+ (Fig. 2A). After 2.5 and 3.5 h of growth, cells grown in the presence of arabinose (WT) showed an increased TPP^+

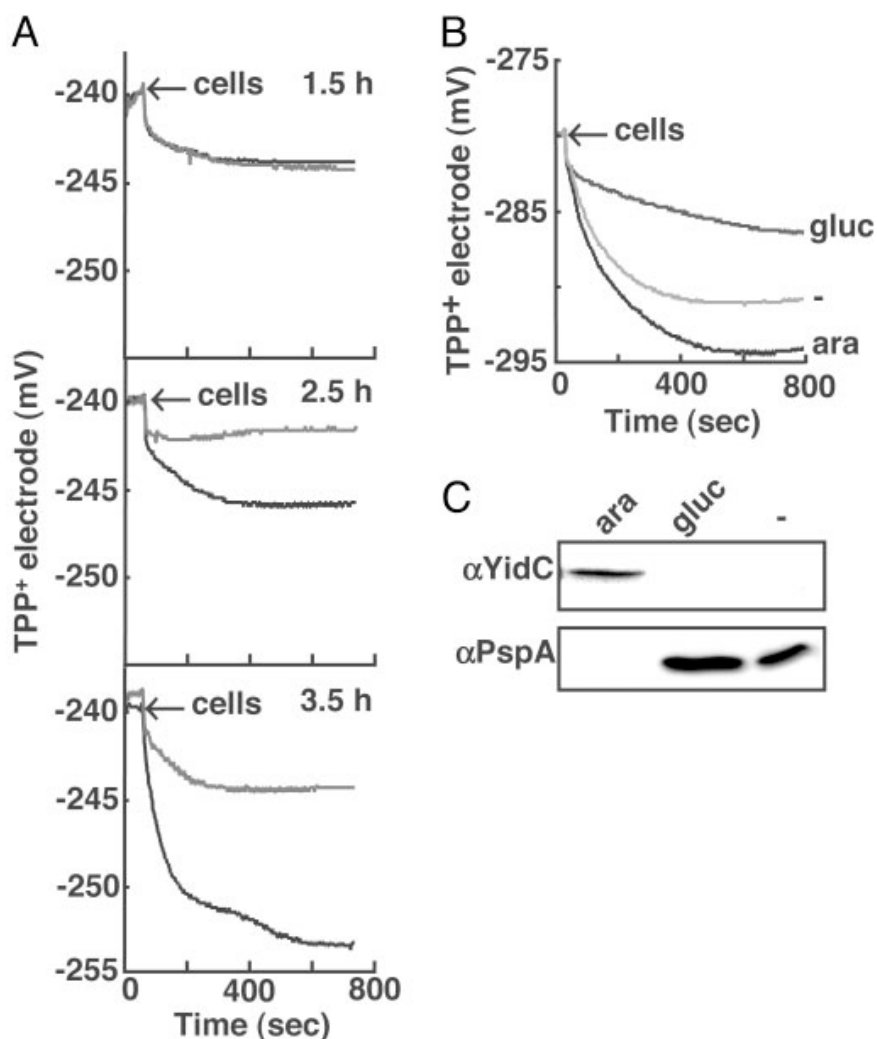

Fig. 2: YidC depletion affects the PMF. (A) Cells were grown as described in Methods and Materials. After 1.5, 2.5 or 3.5 h of depletion, cells were harvested, pretreated and TPP^+ uptake was measured as described in Materials and Methods. (B) Cells were grown overnight in the presence of 0.2% arabinose, washed and diluted in LB medium containing no sugars, 0.1% glucose or arabinose. After 3.5 h the cells were harvested and treated as described above. (C) Cell samples of (B) were taken and analyzed by SDS-PAGE and Western blotting using antibodies against YidC and PspA. The WT signals are shown in black, the YidC \downarrow signals in grey.

uptake as compared to the YidC-depleted cells, indicating that the PMF in the control cells is higher than in the YidC-depleted cells (Fig. 2A). The reduction of the PMF in YidC-depleted cells coincides with the elevated PspA expression at 2.5 h (Fig 1C).

Cells that are depleted for YidC are grown in the presence of glucose instead of arabinose. Addition of glucose to aerobically grown cells has been shown to alter the expression of certain proteins involved in respiration, such as succinate dehydrogenase (189). To exclude the possibility that the diminished PMF in YidC-depleted cells is due to an effect of glucose on the expression of respiratory chain components rather than a direct consequence of the loss of YidC, the TPP⁺ uptake measurements were repeated using JS7131 grown for 3.5 h in the absence of sugars and in the presence of glucose or arabinose. The TPP⁺ uptake of cells grown in the absence of sugars is reduced compared to growth on arabinose, but not as dramatically as in YidC-depleted cells grown on glucose (Fig 2B). Cells grown in the absence of sugars are depleted for YidC and show enhanced levels of PspA (Fig 2C), albeit less pronounced than cells grown in the presence of glucose. In conclusion, the PspA response and concomitantly the reduction of the PMF appear to be directly related to the reduced levels of YidC present in YidC-depleted JS7131.

Depletion of YidC interferes with the membrane assembly of energy-transducing enzymes

To examine the effects of YidC depletion on the PMF in more detail we compared IMVs purified from control and YidC-depleted cells with respect to their ability to generate a PMF *in vitro*. IMVs were energized with either ATP or NADH, and the generation of a PMF was monitored with the pH-sensitive fluorescent dye ACMA. To ensure that the ΔpH is the only component of the PMF the generated $\Delta\psi$ was converted to a ΔpH by the addition of valinomycin (a K⁺ ionophore) in the presence of K⁺ ions. Upon depletion of YidC a clear defect in PMF generation with either ATP or NADH was observed. These effects were progressive during the depletion (Fig. 3). These results are consistent with the *in vivo* measurements and demonstrate that YidC-depleted IMVs have a reduced capacity to generate a PMF.

The effect of YidC depletion on the PMF could be due to an increased proton permeability of the membrane, but alternatively, could be caused by reduced levels of the energy-transducing enzymes, like F₁F₀ ATPase and respiratory chain components.

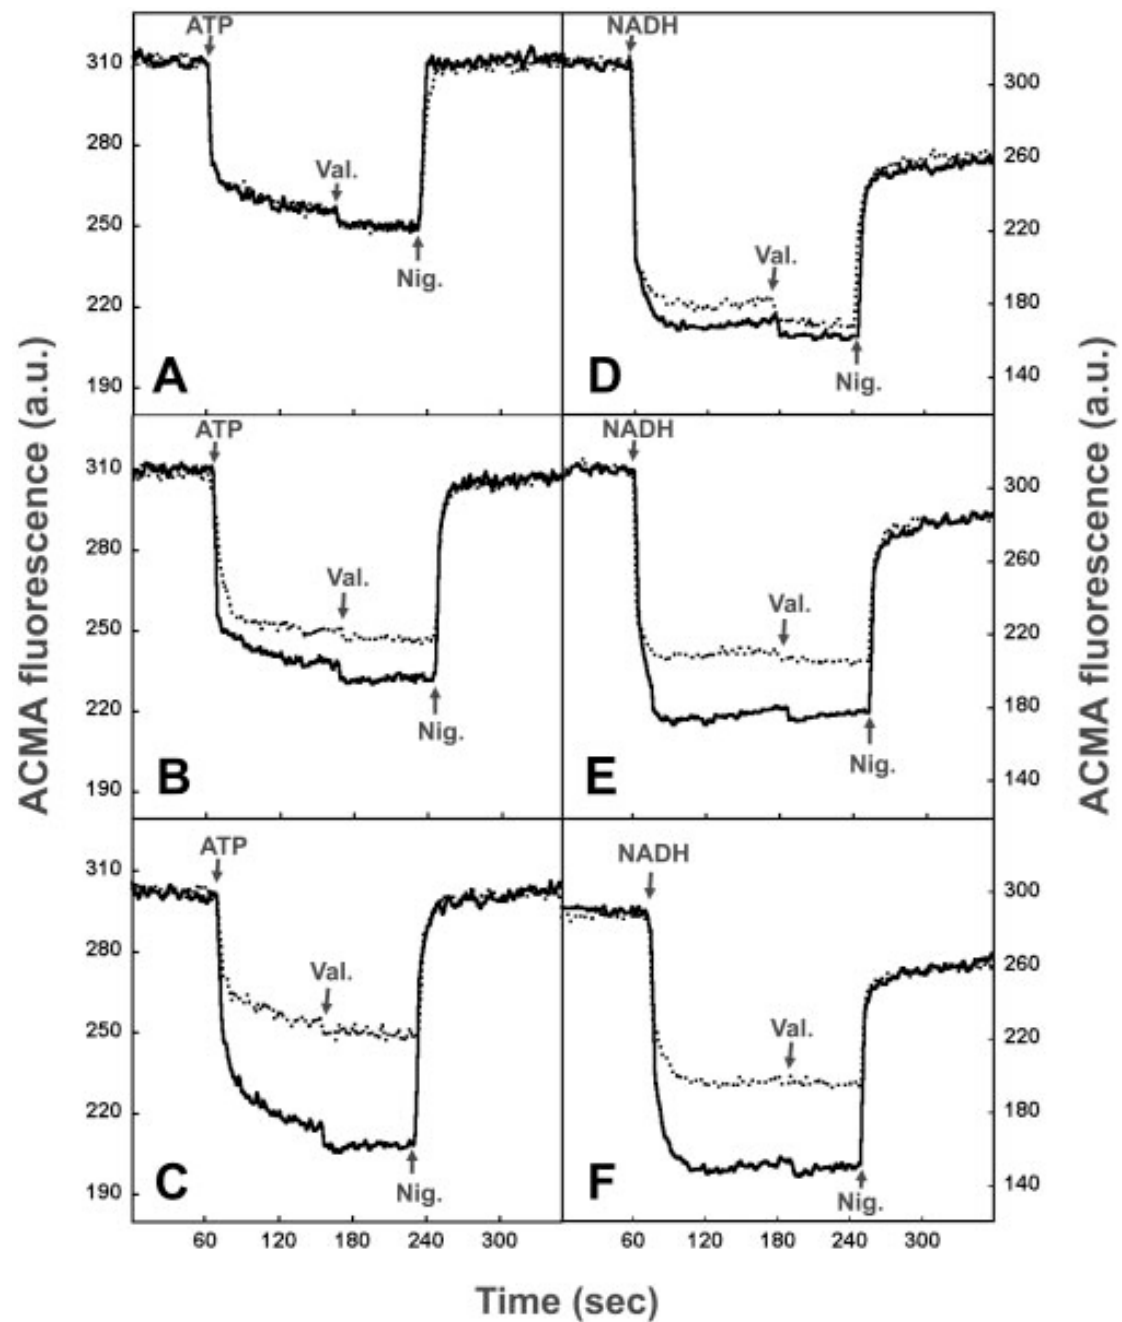

Fig. 3: YidC-depleted IMVs are defective in PMF generation. JS7131 IMVs were prepared from cultures grown for 1.5 (A, D), 2.5 (B, E) or 3.5 (C, F) hours on 0.1% glucose (YidC \downarrow , dotted line) or arabinose (WT, continuous line). The generation of $\Delta\psi$ was determined by monitoring the fluorescence quenching of ACMA. Where indicated, 1 mM ATP (A-C) or 1.25 mM NADH (D-F) was added to the IMVs to generate a PMF. Valinomycin was used at 0.75 μ M to convert the generated $\Delta\psi$ into a $\Delta\psi$. Subsequently, the $\Delta\psi$ was dissipated by the addition of 1.5 μ M nigericin.

Therefore, control and YidC-depleted IMVs were tested for their total ATPase activity. In wild-type IMVs, 95% of this activity can be attributed to F_1F_0 ATPase (M. van der Laan, unpublished data). The ATPase activity of YidC-depleted IMVs gradually decreased as compared to the control resulting in a residual activity of only 26% after 3.5 h (Fig. 4A). This correlated with a drastically reduced amount of the small, ring-forming F_0c subunit of F_1F_0 ATPase in the membrane as detected by

Fig. 4: Depletion of YidC leads to a decreased amount of functional F_1F_0 ATPase complex. JS7131 IMVs were prepared from cultures grown for 1.5, 2.5 or 3.5 h on 0.1% glucose (black bars, YidC↓) or arabinose (white bars, WT). **(A)** Total ATPase activity of IMVs. The data points are the averages of three independent measurements. **(B)** SDS-PAGE and immunoblot analysis of the F_0b and F_0c subunit levels in IMVs.

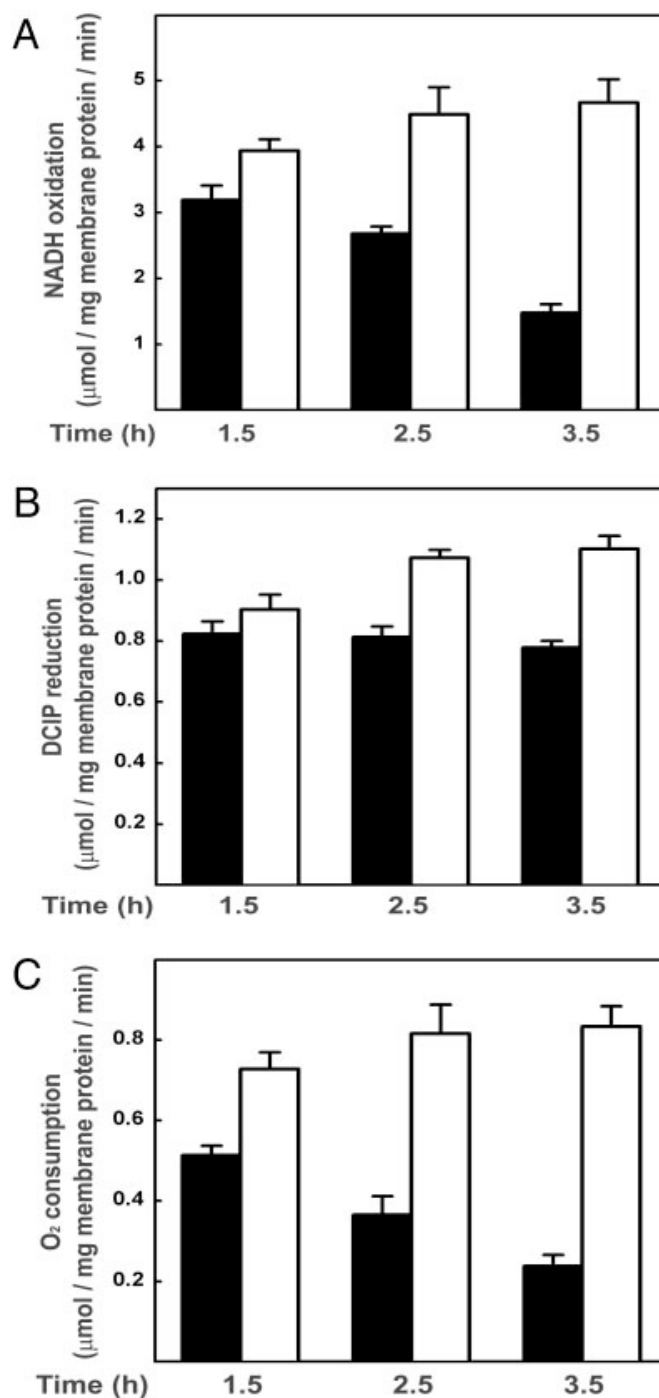

Fig. 5: Depletion of YidC leads to a decreased activity of the respiratory chain. JS7131 IMVs were prepared from cultures grown for the indicated times on 0.1% glucose (YidC↓, black bars) or arabinose (WT, white bars). **(A)** NADH consumption was monitored photometrically as decrease of absorption at 340 nm. **(B)** NADH dehydrogenase activities were determined using Triton X100-solubilized IMVs and the artificial electron acceptor DCPIP. NADH-dependent reduction of DCPIP was monitored photometrically as decrease of absorption at 600 nm. **(C)** Cytochrome *o* oxidase activities were determined using the artificial electron donor system PMS/ascorbate. PMS/ascorbate-dependent O₂ consumption was measured using an oxygen electrode. The data points are the averages of three independent measurements.

immunoblotting (Fig. 4B). The total amount of the F₀b subunit was unchanged but this subunit appeared more susceptible to proteolytic degradation, as an additional lower molecular weight F₀b fragment was observed in the YidC-depleted IMVs (Fig. 4B). Depletion of SecDFYajC, which associates with YidC (187), had no effect on the F₀c and F₀b levels (data not shown).

As described above, YidC depletion also affected PMF generation with NADH. Therefore, we measured the NADH consumption of YidC-depleted and control IMVs as a measure for the total respiratory activity. NADH oxidation activity of YidC-depleted IMVs was ~32% compared to control IMVs after 3.5 h of depletion (Fig. 5A). This suggests that YidC depletion also causes a defect in the respiratory electron transport chain. In these experiments, electron transport from NADH to oxygen is measured. This process involves two multisubunit membrane protein complexes, i.e., NADH dehydrogenase and cytochrome *o* oxidase that are connected by the small electron carrier ubiquinol. To further specify the defect, activities of NADH dehydrogenase and cytochrome *o* oxidase were measured separately. For this purpose, the NADH dehydrogenase activity of detergent-solubilized IMVs was measured through the NADH-dependent reduction of the artificial electron acceptor DCPIP. Remarkably, this activity was hardly affected by the YidC depletion (Fig. 5B) suggesting the presence of a functional NADH dehydrogenase complex. On the other hand, measurements of the cytochrome *o* oxidase activity using the artificial electron donor PMS revealed a strong reduction upon YidC depletion (Fig. 5C). Reduced *versus* oxidized absorption spectra of the IMVs demonstrate that this loss in activity correlates with a reduced amount of the cofactors cytochrome *o* and cytochrome *b*₅₆₂ (Fig. 6), which are bound to the CyoB subunit (subunit I). As shown by immunoblotting, the amount of the ubiquinol-binding subunit CyoA (subunit II) is also decreased upon depletion of YidC (Fig. 6, insert). Strikingly, the reduction of cytochrome *o* oxidase activity quantitatively resembles the effect of YidC depletion on NADH consumption indicating that the reduced electron transport activity is mainly caused by a defect in cytochrome *o* oxidase assembly. Taken together, these results show that depletion of YidC has a dramatic effect on the functional assembly of F₁F₀ ATPase and cytochrome *o* oxidase, which are the major energy-transducing membrane protein complexes in *E. coli* when grown under aerobic conditions (84).

Fig. 6: Depletion of YidC leads to a decreased amount of functional cytochrome *o* oxidase complex. JS7131 IMVs were prepared from cultures grown 1.5, 2.5 or 3.5 hours on 0.1% glucose (YidC↓) or arabinose (WT). Difference spectra (dithionite-reduced minus air-oxidized) of YidC-depleted (3.5 h on 0.1% glucose, dotted line) or WT (3.5 hours of 0.1% arabinose, continuous line) IMVs were recorded. *insert:* IMVs were analyzed by SDS-PAGE and immunostaining using antibodies against cytochrome *o* oxidase.

Discussion

YidC is involved in the biogenesis of IMPs in *E. coli*. The precise function(s) and the essential nature of YidC, however, have remained elusive. In the present study we show that depletion of YidC rapidly and specifically induces the expression of PspA, a stress response that was previously suggested to be triggered by a dissipation of the PMF (169). Consistently, YidC depletion was shown to affect the PMF, which could be attributed to an early and drastic effect on the functional assembly of cytochrome *o* oxidase and F_1F_0 ATPase complexes. The induction of PspA expression upon depletion of YidC proved to be a reliable indicator of a reduced PMF in line with previous suggestion that PspA senses membrane damage and/or a reduction of the

PMF (130, 169). Both *in vivo* and *in vitro* measurements demonstrated a decrease in the PMF that coincides with PspA induction. Under aerobic conditions, the PMF is generated mainly by the respiratory chain membrane protein complexes NADH dehydrogenase and cytochrome *o* oxidase (84). The overall respiratory activity is reflected by the NADH oxidation rate of IMVs, which is drastically reduced in YidC-depleted IMVs. When the functional link between NADH dehydrogenase and cytochrome *o* oxidase is interrupted by solubilization of the membrane and the addition of an artificial electron donor or acceptor, the activities both enzyme complexes can be determined separately. Depletion of YidC leads to a strong reduction of cytochrome *o* oxidase activity, whereas the NADH dehydrogenase activity is hardly affected. However, if cytochrome *o* oxidase activity is lowered, electron transfer will be reduced as well resulting in reduced NADH oxidation by NADH dehydrogenase. Examination of the content of YidC-depleted inner membranes revealed a reduction in the levels of subunit II (CyoA) of cytochrome *o* oxidase and of the subunit I (CyoB)-associated cytochromes *o* and *b*₅₆₂. Interestingly, cytochrome *o* oxidase is homologous to the cytochrome *c* oxidase in mitochondria, which is dependent on the YidC homologue Oxa1p for proper insertion and assembly of its different constituents (104, 220). Oxa1p facilitates the insertion of a variety of mitochondrially-encoded proteins, but of all the substrates tested the CyoA homologue, Cox2p, displays the strictest dependency on Oxa1p for membrane insertion (104).

Saccharomyces cerevisiae mutated in *OXA1* shows respiratory defects not only because of a reduced assembly of the terminal oxidase, but the F₁F₀ ATPase also appeared to be compromised (7, 220). Likewise, we observed that in YidC-depleted inner membranes the ATPase activity was severely reduced. In *E. coli*, the proton-conducting domain, F₀, consist of three subunits (a-c) (reviewed in 190). Depletion of YidC leads to a strong reduction of the amount of the F₀c subunit in IMVs, while the F₀b subunit is normally inserted but seems to be subject to degradation. This degradation of F₀b might be caused by the reduction of F₀c levels, leaving F₀b unassembled. The F₀c is a small IMP with two TMSs, which assembles into a ring structure comprising 10 subunits (122). Purified F₀c subunits self-assemble into a ring-like complex when present in detergent solution (10). However, membrane insertion and assembly of the functional F₀ subcomplex *in vivo* could be more complicated and require assistance, for instance, to ensure a proper timing of

subsequent assembly events. YidC could be involved in the insertion of F_0 components, assembly of the F_0 subcomplex or both. In support of a combined function of YidC, Oxa1p appears to be involved in both insertion and assembly of the F_1F_0 ATPase. In the mitochondria of an *OXAI* deletion strain, the amounts of several F_0 sector subunits were dramatically reduced, subunit c (Atp9) was decreased by ~40%. Interestingly, it was shown that when the intermembrane space AAA protease *YME1* was deleted in combination with *OXAI*, F_1F_0 ATPase subunits were properly localized even in the absence of Oxa1p and 80% of the oligomycin-sensitive ATPase activity could be restored (147). Therefore, it seems that in mitochondria Oxa1p assists and protects the assembling ATPase from proteases without being absolutely required for membrane insertion of the F_0 subunits. Irrespective of the precise molecular mechanism the involvement of the YidC/Oxa1p protein family in the biogenesis of energy-transducing membrane protein complexes seems to be evolutionary conserved as already suggested by Dujardin and co-workers (25).

A reduced integration/assembly of the terminal oxidase is mostly likely the primary cause of the loss of PMF upon depletion of YidC *in vivo*. At present, we cannot exclude that other effects of YidC depletion injure the integrity of the inner membrane and hence cause a dissipation of the PMF. However, since the translocation of presecretory proteins is only marginally sensitive to YidC depletion (205) and the levels of key Sec components are not reduced upon YidC depletion, a jammed or otherwise compromised Sec translocase seems an unlikely explanation for the observed effects.

It has been shown before that the PMF influences the membrane integration and assembly of a variety of membrane protein. The PMF stimulates the insertion and translocation of periplasmic domains of membrane proteins (32, 260), the oligomerization of protomers into complexes (235) and the transmembrane topology of membrane proteins (128). In this respect, the relatively mild effects of YidC depletion on the integration of the Sec-dependent IMPs Lep and FtsQ (205, 230) could be due to the reduced PMF rather than the lack of YidC. Also the putative YidC substrate M13 procoat was shown to require a PMF for proper membrane integration (32). However, it seems unlikely that the M13 procoat insertion defect under YidC-depleting condition is solely caused by PMF reduction, as the insertion of a mutated, PMF-independent M13 procoat was also shown to be impaired upon depletion of YidC (206) although the effect was less pronounced.

Our study identifies two *E. coli* IMPs that strongly depend on YidC for proper biogenesis: CyoA and F₀c. These proteins have in common that they are rather small integral membrane proteins with two closely-spaced TMSs. They both participate in multisubunit oligomeric complexes. These could be natural substrates of the YidC-dependent membrane protein insertion pathway in *E. coli* that is also used by certain phage coat proteins. Future experiments will focus on the mechanism of integration and assembly of CyoA and F₀c.

Methods

Materials

E. coli phospholipids were from Avanti Polar Lipids, Inc., spectinomycin sulfate was purchased from ICN Biomedicals Inc., 9-amino-6-chloro-2-methoxyacridine (ACMA) was obtained from Molecular Probes and Tetraphenylphosphonium chloride (TPP⁺) was from Merck. All other chemicals were purchased from Sigma. YidC polyclonal antiserum was raised in rabbit against purified hisYidC (241) by Agrisera (Umeå, Sweden). Polyclonal antisera against SecD, SecF and SecE were raised in rabbits against the synthetic peptides: IKEELSNGRTVQQAIDEGYRC (SecD), MAQEYTVEQLNHGRKC (SecF) and KGKATVAFAREARTEVRK (SecE), by Agrisera. Antiserum against SecY has been described previously (239). Antisera against PspA, SecA, DnaK, and DegP were kind gifts from J. Tommassen (University of Utrecht, Utrecht, Netherlands), W. Wickner (Dartmouth Medical School, Hanover, NH), P. Geneveaux (University of Geneva, Geneva, Switzerland), and J. Beckwith (Harvard Medical School, Boston, MA), respectively. Antisera against the F₀b and F₀c subunits of the F₁F₀ ATPase were a generous gift from G. Deckers-Hebestreit (University of Osnabrück, Germany), antiserum against cytochrome *o* oxidase was kindly provided by B. Gennis and B. Barquera (University of Illinois, Urbana, IL).

YidC depletion and isolation of inner membrane vesicles

E. coli strain JS7131 (205), in which *yidC* is under the control of the *araBAD* operator/promoter, was grown overnight in Luria Bertani (LB) medium at 37°C supplemented with 0.2% L-arabinose. Cells were harvested, washed with warm LB, diluted to an OD₆₆₀ of 0.05, and further grown with 0.1% glucose to deplete YidC or

Chapter 4

with 0.1% L-arabinose to generate non-depleted control cells. The cultures were grown in volumes of 0.5 l in 2 l baffled flasks. At indicated time points, cells were harvested for Western blot analysis, PMF measurements or the isolation of inverted inner membrane vesicles (IMVs) (55). For IMV isolation 500 OD₆₆₀ units were harvested of cultures grown in volumes of 1 l in 2 l baffled flasks. The harvested cultures had an OD₆₆₀ of ~0.15-0.2 after 1.5 h, ~0.3-0.4 after 2.5 h, ~0.4-0.5 for cultures grown on glucose for 3.5 h, and ~0.8-0.9 for cultures grown on arabinose for 3.5 h.

PMF measurements

The transmembrane electrical potential ($\Delta\psi$) dependent uptake of TPP⁺ by intact cells was measured using a home-made ion-selective electrode. JS7131 cells were permeabilized with 2 mM K-EDTA and 120 mM TrisHCl pH 8.0 at 0.1 g wet weight/ml for 5 min at 37 °C (71). The cells were subsequently washed and resuspended in a buffer of 50 mM potassium-phosphate pH 8.0, 5 mM MgSO₄ and 50 µg/ml chloramphenicol at 15 mg/ml protein. To ensure that the $\Delta\psi$ was the only component of the PMF, 1 µM of nigericin was added and the cells were stored on ice. Uptake of TPP⁺ was monitored with the electrode using 1 mg/ml protein of cells at 25°C in the presence of 500 nM TPP⁺.

The transmembrane pH gradient (Δ pH) in IMVs was monitored using the pH sensitive fluorescent dye ACMA (186). Reaction mixtures at 30° C contained 12.5 µg/ml IMVs and 4 µM ACMA in 50 mM HEPES-KOH, pH 8.0, 50 mM KCl, 2 mM MgCl₂, 1 mM DTT, 0.2 mg/ml BSA (buffer A). Reactions were started by the addition of 1.25 mM NADH or 1 mM ATP, and the ACMA fluorescence was measured in a Perkin Elmer LS50B luminescence spectrophotometer at excitation and emission wavelengths of 409 and 474 nm, respectively.

Enzymatic assays

ATPase activity of IMVs was measured at 37° C as described (143) using malachite green. NADH consumption was determined at 25° C using 10 µg/ml IMVs in buffer A. Reactions were started by the addition of 200 µM NADH and monitored

photometrically at 340 nm using a Carry-Varian Spectrophotometer. Activities were calculated using a molar extinction coefficient ϵ_{NADH} of $6.3 \times 10^3 \text{ l mol}^{-1} \text{ cm}^{-1}$.

NADH dehydrogenase activity was determined at 25° C using 25 µg/ml IMVs and 50 µM of the electron acceptor 2,6-dichlorophenolindophenol (DCPIP) in buffer A containing 1% (w/v) Triton X-100. Reactions were initiated by the addition of 400 µM NADH. DCPIP reduction was monitored photometrically at 600 nm. Activities were calculated using a molar extinction coefficient ϵ_{DCPIP} of $1.5 \times 10^4 \text{ l mol}^{-1} \text{ cm}^{-1}$.

Cytochrome *o* oxidase activity was measured with an oxygen electrode (Yellow Springs Instruments Co, Inc., Yellow Springs, OH) at 25° C (160). Reaction mixtures contained 100 mM potassium phosphate, pH 6.6, 5 mM MgCl₂, 0.2 mg/ml *E. coli* phospholipids, 1.25% (w/v) octylglucoside, 100 µg/ml IMVs and 2.5 mM potassium ascorbate. Reactions were started by adding 10 µM of the artificial electron donor phenomethosulfate (PMS).

Spectral analysis

Cytochrome absorption spectra of IMVs were determined using a Carry-Varian Spectrophotometer. Dithionite-reduced and air-oxidized absorption spectra of IMVs were recorded at 25° C using 0.5 mg/ml IMVs in 10 mM HEPES-KOH, pH 7.5.

Acknowledgements

We would like to thank G. van Eikenhorst and Dr. K. Krab for advice and assistance with the TPP⁺ measurements.
